Foreword

Multiple sclerosis (MS) has a major impact on the lives of patients and their families. Its unpredictable course leaves those affected with an uncertain future. Recent advances in understanding about the disease and its treatment have changed the way that healthcare professionals can help patients and their families. In addition to diagnosing and providing supportive care, treatment now can be directed toward changing the disease course. As a result, MS nurses worldwide are faced with many challenges as they meet the needs of patients in the rapidly changing field of MS. The MS Nurse Specialists Consensus Committee has drawn on research, educational, and practical experiences to develop a new and cohesive model of nursing care in MS—one that will sustain and educate nurses in their clinical practice, promote nursing research, and inspire a new generation of MS nurses as they enter the field. This model is the leitmotif of the International Organization of Multiple Sclerosis Nurses (IOMSN).

A new definition of MS nursing follows. The MS nurse is a competent expert who collaborates with those affected by MS and shares knowledge, strength, and hope. As the role of nurses continues to evolve, there is a need to establish a cohesive model of MS nursing practice along with specific standards for best practice in MS nursing care. Nursing practice aims to both manage and influence the patient’s illness by supporting disease-modifying treatments; facilitating symptoms management; promoting safe, maximal function; and supporting a wellness-oriented quality of life. Activities that are essential to patient care can be grouped into:

- Establishing care
- Continuing care
- Sustaining care

Together, these interwoven areas provide a framework for a comprehensive, cohesive model for MS nursing practice that can be applied to care of all MS patients, regardless of disease classification or level of disability.

This monograph is an updated edition of the earlier version that was created by the Multiple Sclerosis Nurse Specialists Consensus Committee (see page 3 for a complete listing of Committee members, all of whom are nurses specializing in MS care), and now includes valuable new information. As with the previous edition, this monograph is designed to enhance MS nursing care, particularly with regard to disease management, pharmacologic treatment, and nursing research. The information herein was drawn from MS and nursing literature, research in MS and other chronic illnesses, and the years of experience of the distinguished participants in this project. This monograph will assist nurses in fulfilling their universal purpose of providing high-quality, compassionate care of patients and families affected by MS. Specifically, this publication is designed to help nurses:

1. Describe the epidemiology and disease pathology of MS
2. Explain how MS nursing is concomitant to the evolution in diagnostic technology and treatment approaches
3. Identify domains in MS nursing
4. Identify key competencies within each domain
5. Identify the nurse’s various roles in caring for patients and families affected by MS
6. Describe the context of MS nursing practice in optimizing MS treatments
7. Describe medications used for acute, symptomatic, and disease modification in MS with nursing implications
8. Define evidence-based practice in MS nursing
9. Describe limitations and gaps in MS research and proposed work to fill those gaps
10. Identify potential sources of financial support for MS nursing research

We hope the information provides a framework to support the sustained value of the work of nurses who are dedicating their professional careers to the field of MS.

[Editor’s Note: This monograph is supported by an educational grant from Teva Neuroscience]
Introduction

Multiple sclerosis (MS) is a chronic, frequently debilitating, neurological disease that most often affects young adults in the prime of their lives. While nurses contribute significantly to the care of these patients, basic and advanced nursing education has not typically stressed care of patients with chronic and disabling disease. Thus, nurses in MS clinical settings may not always feel prepared to handle the diverse and variable needs of these patients. In addition, rapid advances in technology and medications used for MS, escalating healthcare costs, shorter hospital stays, and an increased emphasis on home care and patient self-care challenge nurses to face increasingly diverse responsibilities in caring for patients with MS. Nurses must not only facilitate the healthcare requirements of these patients but often must also serve as the hub of communication, education, advocacy, and counseling for patients, their families or care partners, and other healthcare professionals.

This monograph is intended to be a tool for MS nurses who are seeking clarification of their roles and responsibilities as well as for nurses interested in pursuing MS care as a specialty. It provides an overview of the MS disease process, proposes a definition and model for MS nursing, identifies medications used to manage MS and control symptoms, and explores the potential for MS nursing research to improve patient care.
Overview of Multiple Sclerosis

MS is a chronic, inflammatory, neurodegenerative disorder that affects the central nervous system (CNS). The disease is characterized by a patchy loss of the myelin sheath that surrounds nerve fibers, visualized as plaques or lesions in the brain and spinal cord. Demyelination disrupts electrical conduction of the nerves in the CNS, producing variable changes in sensory, motor, and cognitive functions. In addition, there may be permanent and irreversible axonal loss accounting for ongoing disability in the spectrum of the disease.

The cause of MS is not known. Research suggests that MS is a consequence of an abnormal autoimmune response to myelin, one that develops after exposure to some environmental agent—possibly a virus—in genetically predisposed individuals. When the immune system is triggered, activated lymphocytes migrate across the blood–brain barrier into the CNS. Once inside, these cells interact with macrophages and other cells, stimulating production of inflammatory cytokines that break down the blood–brain barrier. The combined effects of this autoimmune response cause the demyelination, axonal damage, and scarring seen on cranial and spinal magnetic resonance images (MRIs) in patients with MS. Axonal degeneration and axonal transaction may lead to permanent neurological dysfunction and may begin early in the disease course. In addition, brain atrophy also may occur early and is thought to reflect irreversible tissue damage.

An estimated 400,000 people in the United States and 50,000 people in Canada have MS. People diagnosed with the disease are typically young, and onset typically begins in early adulthood. Women are more than twice as likely as men to be diagnosed with MS.

MS is unpredictable in its overall course, in the type and severity of symptoms experienced by each patient, and in its long-term outcome. Although the disease is seldom fatal, it can be severely disabling, with approximately one third of patients requiring ambulatory assistance within 10 years of their diagnosis. Despite these uncertainties, recent advances in disease modification have brought hope to those affected by MS.

Symptoms and Diagnosis

Symptoms of MS are unpredictable and may be mild, moderate, or severe. Symptoms may appear as an acute attack, also known as an exacerbation or a relapse, or they may become chronic, with clinical and functional deterioration defining disease progression.

Each patient differs in the types and intensity of symptoms, depending on the areas of the CNS that are affected.

Patients with MS may experience fatigue, visual disturbances, weakness, elimination (bowel and bladder) problems, and pain and other abnormal sensations. Other symptoms include vertigo, tremor, speech difficulties, depression, cognitive changes, and Lhermitte's sign (a sudden transient sensation of electric shock that occurs with forward flexion of the neck). Table 1 lists symptoms of MS in order of prevalence.

Prevalence values were determined from a large population-based survey of 697 persons with MS conducted by the Multiple Sclerosis Society of Canada.
based upon attacks separated by at least 1 month, lasting 24 hours or more, and occurring independently of any other disease or condition. These criteria may be modified based on fewer attacks, clinical evidence of only one lesion, or insidious neurological progression suggestive of MS, which requires additional tests such as MRI, positive cerebrospinal fluid (CSF) findings, and/or abnormal evoked potential testing. Since MS remains a clinical diagnosis, the patient’s history, including gender, birthplace, family history, and age when symptoms first began, is critical in the decision-making process. MRI has become essential to diagnosis, detecting lesions, or plaques, as discrete areas of brightness or high intensity, usually in the white matter of the brain and spinal cord. On MRI, MS lesions appear ovoid, and their size may range from a few millimeters to more than a centimeter in diameter. The shape, size, intensity, and location of brain lesions—characteristically, in the periventricular white matter—can also support a diagnosis of MS.

Additional diagnostic procedures may include evoked potential testing (ie, VEPs, brainstem auditory-evoked potentials [BAEPs], or somatosensory-evoked potentials [SSEPs]), which may show slowed nerve conduction even when neurological findings are not elicited on examination. Blood tests can help rule out the presence of other chronic or infectious illnesses as potential causes of MS symptoms, and analysis of CSF may reveal an unusually high number of cells (mostly monocytes) along with qualitative changes in immunoglobulin detected as oligoclonal bands.

**Disease Classification**

According to internationally accepted terminology, the clinical courses of MS are categorized as relapsing-remitting, secondary-progressive, primary-progressive, or progressive-relapsing. Note that three of these classifications consist of relapsing forms of MS, as illustrated in Figure 1. In about 85% of all MS patients, MS follows a relapsing-remitting pattern at onset, with relapses occurring randomly over many years and with minimal accumulation of disability or change in disease progression. In 50% to 70% of patients diagnosed with relapsing-remitting MS, the disease course becomes steadily more progressive over time. This pattern, called secondary-progressive MS, may or may not involve occasional relapses, plateaus, and remissions. Approximately 10% of patients have primary-progressive MS, characterized by a disease course that worsens continuously from onset, with occasional plateaus or temporary improvements. Progressive-relapsing MS is the least common form of MS—afflicting only about 5% of patients—and involves continuous disease progression with superimposed relapses.

Evolution of Multiple Sclerosis Treatment and Nursing Practice

In the second half of the 20th century, the understanding of MS and its diagnosis and treatment evolved from a hopeless prognosis, characterized in 1948 by the National MS Society (NMSS) as the “crippler of young adults,” to a manageable and treatable condition, a new vision of MS. This evolution drew a wide range of healthcare professionals to the field of MS, including specialist nurses, rehabilitation professionals, and counselors.

During the 1970s, 1980s, and early 1990s, MS patient care could be described as a “diagnose and adios” approach, because interventions available at the time could provide temporary relief but had no lasting impact on the disease course (Figure 2). Treatment was mostly palliative and focused on alleviating symptoms and reducing inflammation. Few clinics were devoted specifically to MS, and few nurses were involved in patient care. Even with the advent of MRI technology (about 20 years ago), MS care did not change substantially beyond what Dr. Labe C. Scheinberg described as “MRI and goodbye.”

During the 1990s, MS care improved substantially with the introduction of the immunomodulatory agents interferon β-1a (IFN β-1a; Avonex®, Rebif®), interferon β-1b (IFN β-1b; Betaseron®), and glatiramer acetate (Copaxone®). The availability and efficacy of immunomodulatory agents and advances in diagnostic and monitoring techniques have brought new hope to patients with MS and their families. These changes, along with cost-containment pressures within the healthcare system and expanding prescriptive authority for advanced practice nurses, brought about a dramatic and ongoing expansion in the roles of nurses who treat patients with MS. Treatment has shifted from a focus on crisis intervention and maintenance to a focus on prevention, symptom management, wellness, and empowerment. The nurse has emerged as a pivotal member of a multidisciplinary team who provides education, skills development, and healthcare delivery for patients with MS and their families.

MS nurses now treat patients in primary, acute, specialized, and rehabilitative settings. MS nurses are educators and advocates. Some have prescription privileges, and most work closely with the patient in monitoring and assessing treatment outcomes. MS nurses often initiate, coordinate, or contribute to clinical research. Many are active participants in national and international organizations, such as the International Organization of Multiple Sclerosis Nurses (IOMSN), that have evolved to support professional education, networking, advocacy, and research on behalf of patients with this perplexing and challenging disorder.

As the role of MS nurses continues to evolve, there is a need to establish a cohesive model of MS nursing practice along with specific standards for best practice in MS nursing care. This monograph provides a framework for this model and proposes a philosophy of care that seeks to empower nurses worldwide. The monograph describes many of the responsibilities of MS nursing, encapsulates best practices in patient assessment and treatment, and explores current and potential areas of nursing research in MS—all with the goals of enriching nurses and other professionals and thereby improving the health and quality of lives of all those affected by MS.
Developing a Model of Multiple Sclerosis Nursing Practice

**Definition of a Multiple Sclerosis Nurse**
The MS nurse is a competent expert who collaborates with those affected by MS and shares knowledge, strength, and hope. MS nurses can enhance adaptive and coping skills, facilitate empowerment and a sense of control, and thereby engender hope and positive attitudes among patients with MS and their family members or care partners.16

**Philosophy of Multiple Sclerosis Nursing Practice**
Chronic illness has been described as having a course that can change over time but can be shaped and managed, even if the eventual outcome cannot be modified.17 As applied to MS, nursing practice aims to both manage and influence the patient’s illness by:

- Shaping the disease course by facilitating treatment that interrupts acute episodes and delays the progression of pathology
- Facilitating the management of symptoms and problems that occur in relation to MS
- Enhancing and promoting safe, maximal function
- Supporting wellness-focused quality of life

Because MS is unpredictable in its course and outcome, the philosophy of MS nursing must be flexible, fluid, dynamic, and responsive to changes in the patient’s physical and emotional status. In addition, MS nursing care must recognize, react to, and respect demographic, socioeconomic, and cultural boundaries with care that is comprehensive, empathic, and ultimately holistic.18

In this section, to assist in understanding nursing practice issues, MS is viewed across a trajectory from prediagnosis or early diagnosis to advanced-stage disease. Practice issues are discussed for patients grouped as follows:

- Those with relapsing-remitting MS
- Those with progressive MS, including those with primary-progressive, secondary-progressive, or progressive-relapsing disease
- Those with advanced MS, including patients who have become severely disabled within a brief or substantial length of time

**Practice Areas**
Activities that are essential to the care of patients with MS can be grouped into three main areas:
1. Establishing care
2. Continuing care
3. Sustaining care

Together, these three interwoven areas provide a framework for a comprehensive, cohesive model for MS nursing practice that can be applied to care of all MS patients, regardless of disease classification or level of disability (Figure 3). Although specific activities within each area may be the same for each patient, the emphasis may shift according to the stage of disease.

Establishing care is the first step toward building relationships and encouraging open communication with patients and their families or care partners. Components of establishing care include building trust, establishing partnerships, determining information needs,
sharing information, and assessing each patient’s support network. These activities provide a foundation that promotes empowerment, encourages positive attitudes, and fosters hope, ultimately contributing to the establishment of a strong therapeutic alliance between nurses and those receiving care.

Continuing care focuses on cultivating patient health. As part of continuing care, nurses serve as educators, counselors, and advocates. Nurses teach patients practical approaches for managing disease symptoms and medication side effects, stressing the importance of adherence to treatment. Nurses also help patients implement self-care strategies, such as self-injection, symptom management, and wellness strategies focused on diet, exercise, and coping with stress. Self-care strategies can enhance patients’ health and give them a sense of control over their illness. As part of continuing care, nurses may also assist patients with family and vocational issues, and guide patients through the many life- and health-related uncertainties associated with MS.

Sustaining care focuses on maintaining patient well-being. In sustaining care, MS nurses coordinate referrals, identify community and information resources, and serve as consultants as patients’ and families’ needs change. Sustaining care also calls for the establishment of collaborative liaisons between MS nurses and other healthcare professionals—for example, neurologists, primary care physicians, speech and language pathologists, rehabilitation specialists, psychologists, and social workers—as dictated by the patient’s physical and emotional needs. In addition, MS nurses may establish liaisons outside the healthcare team, to include government services, synagogues or churches, and other organizations that can provide assistance and support for patients with MS.

**Practice Areas Across the Disease Trajectory**

**Patients With New or Probable Diagnoses**

For patients with a new diagnosis of MS or symptoms that strongly suggest MS, the nurse’s priority is to establish care. Nurses should be aware that patients differ in their reactions to diagnosis.18,19 Some patients experience grief and shock; some, denial; others may feel relieved to find an explanation for their symptoms. Initially, some patients may be unable to absorb much specific information about the disease and treatment options; others may want as much information as possible. Special attention may be needed for patients who are awaiting confirmation of a probable diagnosis, a process that may be prolonged and frustrating.19 As part of building trust and open communication, nurses need to carefully assess patients’ reactions, coping mechanisms, and information needs.

**Patients With Relapsing-Remitting Multiple Sclerosis**

For patients with relapsing-remitting MS, the main focus is on continuing care. Sometimes, however, activities toward establishing care apply—for example, when a patient has been symptom free for months or years. Research suggests that a relapse represents an “interruption” that precipitates a need for new information to help the patient cope.20 MS nurses will likely find themselves counseling patients to help them contend with the disappointment and discouragement associated with a relapse. Nurses can reestablish communication and reassess information needs to pave the way for the continuing care needs of these patients.

As part of continuing care for patients with relapsing-remitting MS, nurses need to emphasize the importance of early and sustained treatment with the disease-modifying agents. They can help patients establish realistic expectations and explore treatment options. Nurses can also help patients make informed decisions about the use of complementary or alternative therapies.

Nurses also serve as advocates to ensure that patients have timely and adequate access—through insurance or other healthcare programs or through industry-supported programs—to medications, adaptive equipment, and supplies. Nurses will need to help patients and families cope with the major responsibilities of managing symptoms and complications of MS while maintaining “normal” lives and dealing with the ordinary events and experiences of living.17 Encouraging patients to develop support networks, for example, through participation in an MS support group, can help.
In sustaining care of patients with relapsing-remitting MS, nurses must recognize the tremendous burden and responsibility that the disease represents to patients and their families. Nurses have to advocate for adequate insurance entitlements and appropriate access to care. They may need to defend patient autonomy with regard to treatment decisions and self-care activities. Sustaining care for patients with relapsing-remitting MS requires continuous evaluation of patients’ physical, cognitive, and emotional status. Specific changes, for example, in mobility or cognition, should be assessed and treated when they become evident and when they interfere with activities of daily living. In addition, treatment outcomes and the patient’s self-care abilities should be monitored. If patients are doing well on treatment, positive reinforcement can help continue that pattern; if patients are not adhering to treatment, nurses should determine impediments to adherence and initiate strategies to reverse this trend.

Patients With Progressive Multiple Sclerosis

The nursing care needs of patients with progressive MS are often complex. Sustaining patient trust and maintaining open communication are crucial to effective practice. If the disease worsens, the patient’s physical, cognitive, and emotional needs should be continually reevaluated. Safety issues are the key concern. A caregiver or family member may need to be enlisted to assume responsibilities for activities of daily living and other interventions previously managed by the patient. The nurse can assist with training the caregiver and counseling the patient through this change in status. If disability increases, continued counseling and healthcare interventions can help the patient adapt and adjust. Rehabilitation efforts may be employed to reduce the severity of certain symptoms and improve patient independence.

Patients With Advanced Multiple Sclerosis

For patients whose disease has become more advanced, nurses must redefine therapeutic partnerships with patients and with family members or care partners who ensure that the patient’s daily needs are met. If the patient’s condition warrants home healthcare or admission to a nursing home, the nurses who provide this care will need to establish new therapeutic relationships. For patients with advanced disease, it is especially important for care to be planned and implemented with attention to individual patient preferences, cultural mores, and previous lifestyle. In addition, because case management issues associated with advanced MS are often complex, nurses need to serve as advocates for quality care.

Continuing care needs of patients with MS shift to providing comfort, ensuring safety, and preventing complications. For example, patients with impaired mobility need interventions that prevent pressure sores. For patients who have difficulty speaking, alternate communication methods need to be devised. For patients who have lost the ability to swallow, alternative feeding methods will be necessary. Although these patients may not be able to care for themselves, they require recreation, stimulation, and support of their daily living activities. These requirements are universal for all people and are especially important for those facing daily losses in function, financial and emotional security, and self-esteem.

As part of sustaining care for patients with more advanced disease, these patients and their families require information and counseling on various issues, including the acceptance of progression of their disease, the need for life planning and advance directives, nursing home placement, and hospice care. Patients may need an opportunity to talk openly and honestly about their feelings. Nurses must be alert to signs of despair, helplessness, and hopelessness in their patients and must make appropriate referrals. Depression and suicide are real phenomena in MS. Patients with advanced disease and their families are often dealing with end-of-life issues, and nurses will want to consider palliative care options used by other patient populations.
Domains and Competencies of Multiple Sclerosis Nursing

The purpose of this section is to continue defining a model for MS nursing by identifying domains and competencies that describe the unique specialty of MS nursing. This model also helps to define best practices.

The domains of MS nursing are the particular areas of knowledge, expertise, and influence provided by nurses who care for patients with MS. Competencies are defined as the specific types of knowledge and skills that fit within and support the nursing domains. Domains and competencies described here have been selected to encompass care of patients over the full life-span trajectory of people with MS—that is, across the continuum from the newly diagnosed patient to advanced-stage disease.

Together, these domains and competencies define the standards and scope of MS nursing practice. They can serve as a guide for nurses who currently specialize in MS care or who plan to pursue this specialty.

Multiple Sclerosis Nursing Domains

- Establish therapeutic partnerships with MS patients, their families, and other health professionals on the patient’s professional healthcare team.
- Perform comprehensive assessments to gauge each patient’s level of functioning, identify the patient’s needs and preferences, understand the patient’s learning style, appreciate the patient’s lifestyle, and get to know the patient’s family.
- Formulate a collaborative treatment plan, taking into account the patient’s symptoms, level of disability, need for disease-modifying agents, and need for sustained or prolonged care.
- Initiate and facilitate a treatment regimen by educating the patient about disease-modifying medications; teaching self-injection; serving as a patient advocate; helping the patient to overcome physical, cognitive, or other obstacles to treatment; and administering treatment when necessary.
- Monitor the patient’s treatment outcomes, including adherence; self-care, self-efficacy, and responsibility; side effects and adverse effects of medications; lifestyle changes; and quality of life.
- Sustain therapeutic alliances with the patient, family members or care partners, and other health professionals on the patient’s healthcare team.
- Maintain and broaden nursing competencies, eg, develop new skills; enhance MS knowledge; and initiate, coordinate, or participate in MS research.

Knowledge-Based Competencies

To carry out activities of these various domains, MS nurses should have solid, comprehensive, and current knowledge in the following areas:

1. Course and pathology of MS, including the trajectory of MS across the life span
2. Pharmacology of therapeutic agents used for acute, symptomatic, and disease-modifying treatments
3. Use of complementary and alternative therapies in MS
4. Use of evaluation tools for monitoring outcomes
5. Basics of rehabilitation practice
6. Community resources—information and resources for patients and families
7. Educational principles, including age-specific learning techniques
8. Psychosocial issues, such as cultural and ethnic considerations, coping, and gender and sexuality issues
9. Reimbursement processes (insurance and managed care plans, Medicaid, Medicare, pharmaceutical industry programs)
10. Healthcare and education strategies that encourage wellness and health promotion
11. Professional expertise, for example, knowledge of nursing theory and models, assessment tools, current technologies, technical nursing skills, and professional organizations

Skill-Based Competencies

Skills necessary to professional nursing care of patients with MS include the following:

1. Communication
   a. Listen to patient, family, other members of the healthcare team
   b. Collaborate with other healthcare providers
   c. Network
d. Negotiate  
e. Delegate  
f. Document  

2. Assessment  
   a. Recognize physical care requirements  
   b. Perform neurological assessment  
   c. Perform functional assessment  
   d. Perform psychological, sociological, and cognitive assessments  
   e. Recognize culture-specific needs  
   f. Detect acute and chronic changes in health  

3. Counseling  
   a. Provide anticipatory guidance (foresee and forestall problems)  
   b. Define patient’s, family’s, and nurse’s limits and responsibilities  
   c. Listen, motivate, inspire hope, and put MS “in its place”  
   d. Problem solve  

4. Education and teaching  
   a. Serve as role model for patients, family members, other nurses, and other members of the professional healthcare team  
   b. Serve as a mentor and preceptor  
   c. Increase awareness about MS in the community  

5. Advocacy  
   a. Negotiate within the healthcare system  
   b. Promote self-care  
   c. Participate in research  
   d. Establish benchmarks of nursing care  
   e. Examine outcomes of nursing practice  

**Matching Nursing Competencies to Nursing Domains**  

Table 2 shows how specific skill-based competencies can be matched to MS nursing domains, providing a comprehensive and practical illustration of the scope of MS nursing practice. For example, as part of establishing therapeutic partnerships, nurses listen to and communicate with patients and other health professionals. Nurses assess the patient’s psychological, social, and cognitive abilities and maintain sensitivity to cultural, ethnic, and gender issues. Nurses provide anticipatory guidance; establish limits and responsibilities of care for patients, family members, and healthcare professionals; and listen, motivate, and inspire hope in initiating treatment. Education about the disease and about effective treatment and management of symptoms is an essential component of developing nurse–patient partnerships. Furthermore, as part of establishing therapeutic partnerships, nurses may need to serve as advocates by negotiating within the healthcare system—ensuring that patients get the medications, equipment, and resources they need—and by promoting patient self-care.

As part of monitoring outcomes, MS nurses listen and communicate and must continuously assess and document the patient’s functional, psychological, sociological, and cognitive status over time (Table 2). In addition to monitoring the patient’s general health status, nurses must be acutely aware of the appearance of, or changes in, symptoms. Nurses also provide counseling to motivate patients and encourage hope. They provide education about monitoring treatment, serving as role models for patients and families and as mentors and preceptors for their less experienced peers.

Many of the specific skills identified in Table 2 apply across multiple domains. For example, anticipatory guidance is crucial not only for establishing strong therapeutic relationships but also for formulating, initiating, and facilitating treatment. Similarly, the nurse’s capacity to listen, motivate, and inspire hope is essential not only to establishing therapeutic partnerships and formulating treatment plans but also to monitoring treatment outcomes and sustaining therapeutic alliances. Recognizing the patient’s physical care needs is obviously important to performing a comprehensive assessment, but it is also part of formulating and implementing treatment and monitoring treatment outcomes. These examples illustrate the continuity that exists both within and across domains and competencies.

</table>
Role of the Nurse in Pharmacologic Therapy of Multiple Sclerosis

As a primary source of information for patients and families affected by MS, nurses are in an optimal position to provide education about medications. Nurses can provide practical information about indications, effectiveness, and side effects, thereby facilitating patients’ treatment decisions, clarifying any misconceptions, and ensuring proper use of medications.

MS nurses also play a substantial role in monitoring adherence. Once a particular medication or medication regimen is started, nurses must know how to assess treatment responsiveness and what side effects to be mindful of. Nurses also serve as advocates, working with insurance companies, managed care organizations, Medicaid and Medicare, and pharmaceutical support programs to make sure that patients can obtain and receive reimbursement for the treatments prescribed.

Medications for MS include:

• Episodic treatments—those used to shorten relapses
• Symptomatic treatments—those used to minimize or control specific symptoms such as spasticity, bowel and bladder problems, and fatigue
• Disease-modifying treatments—immunomodulatory therapies and other agents developed to reduce the frequency and severity of relapses and slow disease progression

This section lists and discusses many of the medications used for the management of MS, along with specific nursing considerations for each medication.

Episodic Treatments

In patients with MS, a relapse—also known as an acute attack or an exacerbation—is defined as an episode of new or worsening MS symptoms that lasts more than 24 hours and is not related to metabolic changes (eg, due to fever or intercurrent illness) or steroid withdrawal. Typically, an acute relapse tends to progress over a few days, reaches its peak within a week, then slowly resolves. Relapses often lead to a change in the patient’s functional status, and resolution may require as long as 6 months.

There is no established standard for management of relapses. Treatment decisions are determined by the healthcare provider on an individual basis. Depending on specific symptoms, no treatment may be suggested—for example, for patients with mild sensory attacks and no functional decline. Most patients who are experiencing acute relapses are given high-dose corticosteroids, usually intravenously but sometimes orally. Treatment is based on the practice patterns of the physician caring for the patient. Unfortunately, there is a paucity of literature documenting the superiority of one route of administration over the other.

These drugs reduce the inflammation in the central nervous system and may help reestablish the integrity of the blood–brain barrier, thereby hastening improvement of symptoms.

Intravenous methylprednisolone (IVMP) is consistently the treatment of choice. Initially, this anti-inflammatory corticosteroid is given at high, intermittent doses over 3 to 5 days. IVMP can be given in the hospital or at home, and may or may not be followed by a gradually tapering dose of an oral corticosteroid.

During steroid treatment, patients and families need to know what to expect. Nurses can provide education about realistic outcomes and side effects that demand medical intervention. Typical side effects include increased appetite, gastrointestinal upset, nervousness or anxiety, and insomnia. Facial flushing, urinary frequency, and taste disturbance may also accompany corticosteroid treatment. Patients should be encouraged to call if they experience anxiety or insomnia. Other side effects that may warrant monitoring and medical treatment include glycosuria and severe mood changes or mood swings. Patients should be advised to limit salt and sugar intake while on corticosteroid treatment, and patients taking immunomodulatory agents (the interferons or glatiramer acetate) should be told not to stop these medications while receiving IVMP or any other.
treatment for a relapse. During the time of a relapse, it is important to assess whether patients would benefit from other interventions, such as adaptive equipment, during a relapse. For example, for patients who have difficulty walking during an attack, a cane or walker can provide a safe, energy-conserving mobility device. Nurses may also want to discuss temporary modifications to patients’ work-related and physical activities.

Symptomatic Treatments
Managing the ongoing symptoms of MS is challenging, but effective management can dramatically improve the patient’s quality of life. Fatigue, elimination problems, and other common symptoms can be controlled or reduced through education, counseling, and rehabilitation measures. When these strategies are not sufficient, pharmacotherapy may be considered.28

Table 3 lists medications used for symptom management in MS. Generic drug names are given, along with specific nursing implications associated with their use, for treatment of various symptoms. The table is not intended to be exhaustive; the most common or problematic symptoms are discussed here, but others that may benefit from nursing intervention include tremor; weakness, vertigo, and sexual dysfunction. Excellent reviews of the strategies and medications used to manage these symptoms are available for guidance.26,28

The first step in symptom management is to determine factors that are causing or contributing to symptoms. Concomitant medications and concurrent illnesses or other medical conditions may produce new symptoms or alter the severity of the symptoms. If pharmacologic treatment is needed to alleviate symptoms, some general “rules of thumb” apply. First, it is essential to determine if any contraindications, such as other medical conditions or concomitant medications (including over-the-counter medications and alternative treatments), preclude treatment with a particular agent. Second, nurses need to convey what outcomes patients should anticipate and what side effects may occur—this can help reinforce positive therapeutic relationships and can help optimize symptom management. Third, patients need to be encouraged to follow up, so that nurses can confirm that medications are working properly and intervene if unexpected outcomes or intolerable side effects occur. Nursing strategies such as dose escalation and dose titration can help patients avoid side effects and increase tolerance to treatment.

Fatigue
Fatigue is the most common—and often the most disabling—symptom associated with MS.28 Fatigue in patients with MS may occur in several different forms—as activity-related fatigue; as fatigue associated with deconditioning, depression, or neuromuscular exhaustion; or as a lassitude known as “MS fatigue.” Treatment of fatigue requires effective energy management, medications, or both. Nurses can suggest behavioral changes such as conditioning programs, exercise, and improved nutrition.29 Patients can be referred to an occupational therapist, who can teach them about and help them implement energy-conservation techniques.

Drugs that can provide relief include CNS stimulants such as methylphenidate (Ritalin®) and modafinil (Provigil®).30,31 Patients should be advised that these medications may cause nervousness, restlessness, and insomnia. Antidepressants such as fluoxetine (Prozac®) and an antiviral agent, amantadine (Symmetrel®), may also be effective for fatigue.30,32 Recent literature has also documented the benefit of conditioning programs with graded exercise to reduce fatigue.29

Bladder Dysfunction
Bladder dysfunction results from pathology to nerve pathways controlling detrusor function, sphincter function, or a combination of both.33 Symptoms of bladder dysfunction—urinary hesitancy, frequency, urgency, or incontinence—affect many people with MS. Patients may attribute these problems to the effects of aging or childbirth, and simply accept them as such rather than as modifiable symptoms of MS, but they should be informed that bladder symptoms can be managed. Dysfunction may manifest as failure to store urine, failure to empty urine, or both. Urinary tract infection may be a contributing factor and should be ruled out or treated appropriately before initiating other treatment.

Effective pharmacologic treatments include anticholinergic agents, antimuscarinic agents, and β-blockers.30,34

</tbody>
</table>
A bladder training program that includes education, elimination of bladder irritants such as caffeine and aspartame, scheduled voidings, and positive reinforcement can also improve bladder functioning and quality of life. Medications include oxybutynin (Ditropan®, Ditropan® XL), a transdermal patch (Oxytrol®), tolterodine (Detrol®), and trospium chloride (Sanctura™). Patients may also require bladder emptying with either intermittent or permanent placement of a catheter.

### Bowel Dysfunction

Patients with MS may have bowel problems that range from constipation to bowel urgency and involuntary bowel movements. Constipation is the most common, and involuntary bowel movements are perhaps the most distressing.

Constipation is best managed with preventive measures, including a high-fiber diet, adequate fluid intake, exercise, and an established bowel program. The nurse can guide and facilitate a bowel program with education and support. If medication is indicated, bulk formers (such as psyllium) or softeners (such as docusate) may be prescribed. If a stimulating laxative is needed, a mild compound such as milk of magnesia may work best. Stronger stimulants and stimulating suppositories or enemas should be regarded as occasional treatments or tools to get a bowel program started—their use on a regular basis should be avoided.

Patients with bowel urgency may benefit from treatment with an anticholinergic agent such as oxybutynin (Ditropan®) or an antimuscarinic agent such as tolterodine (Detrol®) or trospium chloride (Sanctura™). These medications have antispasmodic effects that can ease uninhibited bowel spasms that contribute to urgency. Bulk-forming agents, with a regular bowel routine, can also reduce bowel urgency.

### Pain

Pain in MS may be neuropathic or neurological in origin and acute or chronic in duration. Because the pain associated with MS differs from that typically associated with injury, standard pain medications such as aspirin, nonsteroidal anti-inflammatory agents, and narcotic analgesics do not provide relief.

Examples of acute pain that occur frequently in patients with MS are *trigeminal neuralgia*, a sharp, stabbing pain in the face, and a burning, aching sensation known as *burning dysesthesia*. Pharmacologic treatments that can provide relief include the anticonvulsants carbamazepine (Tegretol®, Carbatrol®), gabapentin (Neurontin®), and lamotrigine (Lamictal®).\(^{30,35}\) Though often effective for pain, some anticonvulsants may cause sedation; slow titration can minimize this side effect. Tricyclic antidepressants such as amitriptyline (Elavil®) may relieve pain and can be especially helpful for dysesthesias; they may act by stopping pain conduction through the nerves.\(^{36}\) Capsaicin cream, a topical agent with few side effects, can also soothe dysesthesias.\(^{30}\) A transdermal delivery system, a lidocaine (Lidoderm®) patch, may provide patients with sustained relief if oral medications are partially effective or ineffective.

Chronic pain in patients with MS often manifests as a “pins and needles” sensation, or as a burning, aching pain. Chronic pain is treated with the same medications used for treatment of acute dysesthesias.

Patients with MS also may experience pain as a result of muscle cramping or abnormal musculoskeletal stresses. Musculoskeletal pain can be alleviated by supportive interventions such as an ankle–foot orthosis, or appropriate positioning or seating devices to maintain/sustain appropriate body alignment.

### Spasticity

Another common symptom, spasticity, is a major factor in decreased mobility among patients with MS. Spasticity can manifest as stiffness or spasms, may involve pain and discomfort, and may interfere with daily activities. Regular stretching and exercise can reduce stiffness and improve function, but pharmacologic treatment is often necessary.

Effective antispasmodics include baclofen (Lioresal®), a \(\gamma\)-aminobutyric acid (GABA) antagonist, and tizanidine (Zanaflex®), an \(\alpha_2\)-adrenergic agonist. The anticonvulsant medications diazepam (Valium®) and clonazepam (Klonopin®) may also be helpful in combination with other medications.\(^{36}\) For many of these medications, it is best to start at low doses, then titrate up, to improve tolerability. Maximizing the dose at bedtime, usually a
time of maximal spasticity, is a useful strategy for managing both spasms and the sedative effects of some anti spasmodics. Baclofen is among the most commonly used medications for spasticity, but the drug may cause weakness or sedation. If weakness limits the use of baclofen, tizanidine is a viable alternative. Baclofen and tizanidine may be used in combination as well. For spasticity that is severely disabling and not responsive to oral drug therapy, an injection of botulinum toxin (Botox®) can provide temporary relief but may need to be repeated.

**Depression**

Both clinical depression and a similar, less severe emotional distress are common in patients with MS. Between 36% and 54% of patients with MS experience major depression at some time during their illness—a rate much higher than that seen in the general population. Rates of suicide among people with MS are also much higher than those seen in the general population. MS nurses must be aware of the symptoms of depression and assess patients with each contact. Appropriate referrals for counseling or psychiatric therapy and recommendations for pharmacologic treatment should be made as needed.

If depression is suspected, certain contributing factors must be considered. Some medications, including baclofen and benzodiazepines, which are used for symptom management, may be associated with depression. Patients should be screened for depression before starting treatment with disease-modifying therapy, and any depressive symptoms should be treated before or during therapy. Note that other medical conditions, such as hypothyroidism, can contribute to a depressed affect and should be ruled out or treated, as appropriate.

An array of medications is available to alleviate depression. Selective serotonin reuptake inhibitors (SSRIs), such as fluoxetine, sertraline (Zoloft®), escitalopram oxalate (Lexapro®), citalopram HBr (Celexa®), paroxetine (Paxil® or Paxil CR™), and duloxetine hydrochloride (Cymbalta®), are frequently prescribed. Tricyclic antidepressants, including amitriptyline and nortriptyline, are useful, especially if sleep disturbance accompanies depression. Atypical antidepressants such as venlafaxine (Effexor®) and bupropion (Wellbutrin®) may also be prescribed.

**Medications Used for Disease Modification**

**Immunomodulatory Agents**

Evidence that MS is more than a demyelinating disease—that axonal transaction is the pathology underlying permanent disability, occurs early in the disease course, and causes irreversible damage—has given major impetus for the early and aggressive treatment with immunomodulatory agents.

IFN β-1a (intravenous and subcutaneous), IFN β-1b, and glatiramer acetate are now fundamental components of treatment for relapsing forms of MS. IFN β-1a and IFN β-1b are recombinant proteins that may exert their effects by inhibiting inflammation and the migration of white blood cells across the blood–brain barrier. In contrast, glatiramer acetate, a synthetic polypeptide thought to resemble myelin basic protein, may act by stimulating immune suppressor lymphocytes that then release anti-inflammatory cytokines. Glatiramer acetate may also compete with myelin antigens for binding to antigen-presenting cells, thereby preventing autoimmune reactions that lead to demyelination.

Table 4 summarizes key information for each immunomodulatory agent, including injection routes, findings from recent clinical trials, and resources for further information. As shown in clinical trials, these immunomodulatory agents can modify disease progression, reduce future disability, and improve quality of life for patients with relapsing-remitting MS. The clear benefit of these agents prompted the National Multiple Sclerosis Society to release a consensus statement recommending early intervention and continued treatment for all patients with MS (Table 5). Thus, for most patients with a confirmed diagnosis of MS (that is,

patients who have experienced two or more attacks separated by time and space, have clinical evidence of two or more lesions in the white matter of the CNS, and fulfill criteria described earlier\(^8\), the question is not whether to treat with an immunomodulatory agent but, rather, which agent to use.

Currently, patients experiencing only one neurological episode suggestive of MS along with MRI data indicative of MS are considered to be at high risk for a diagnosis of MS and immunomodulatory therapy is indicated.\(^59\)

Data from a trial exploring the potential value of initiating treatment at the first sign of clinical demyelination demonstrated that IFN \(\beta-1a\) can significantly delay the development of clinically definite MS in patients who have had only one relapse, sometimes referred to as “monosymptomatic” presentation.\(^44\) These findings provide further evidence and impetus for early initiation of immunomodulatory therapy and suggest that, for some patients, treatment may need to be considered before a second relapse has occurred.

This premise of early treatment has been borne out by data demonstrating that long-term adherence to immunomodulatory therapy that is initiated early in the disease process benefits patients with MS. Among all available immunomodulatory agents, glatiramer acetate has the longest record of patient information stemming from the original trial.\(^60,61\) In the pivotal trial examining the efficacy of glatiramer acetate over time, the annual relapse rate declined by 72% over 6 years of treatment, from an average of about 1.5 per year at entry to 0.23 (or an average of 1 every 4+ years).\(^53,54\) Furthermore, 69.3% of glatiramer acetate–treated patients experienced no further change in disability or improved at least one step on the Expanded Disability Status Scale (EDSS).\(^53\) Importantly, a separate analysis comparing outcomes in patients who received glatiramer acetate throughout the trial with those in patients who received placebo for about 30 months demonstrated that delaying treatment was detrimental, in terms of both the frequency of relapses (significant difference between the groups during years 1 and 2) and the risk of disability as measured by a decline in one or more EDSS steps (which was significantly greater in patients in whom therapy was delayed).\(^54\)

---

**TABLE 5. Recommendations of the Medical Advisory Board of the National Multiple Sclerosis Society on the Use of the Immunomodulators\(^58\)**

- Initiation of therapy with an immunomodulator is advised as soon as possible following a definite diagnosis of MS with a relapsing course, and may be considered for selected patients with a first attack who are at high risk for MS.
- Patients’ access to medication should not be limited by the frequency of relapses, age, or level of disability.
- Treatment is not to be stopped while insurers evaluate for continuing coverage of treatment.
- Therapy is to be continued indefinitely, except for the following circumstances: there is a clear lack of benefit; there are intolerable side effects; new data reveal other reasons for cessation; better therapy becomes available.
- All of these FDA-approved agents should be included in formularies and covered by third party payers so that physicians and patients can determine the most appropriate agent on an individual basis—failure to do so is unethical and discriminatory against a very small percentage of patients.
- Movement from one immunomodulatory drug to another should be permitted.
- Immunosuppressant therapy with Novantrone\(^\circledR\) (mitoxantrone) may be considered for selected relapsing patients with worsening disease.
- Most concurrent medical conditions do not contraindicate use of the immunomodulatory drugs.
- None of the four therapies has been approved for use by women who are trying to become pregnant, are pregnant, or are nursing mothers.

All of the available immunomodulatory agents have side effects (Table 4). For example, some cause injection-site reactions, which usually are mild and self-limiting. Some side effects, such as the flu-like symptoms seen with the interferons, may persist for several months.\textsuperscript{59,62} Glatiramer acetate appears to have the mildest side effect profile; rarely, it may cause a transient, benign reaction characterized by chest tightness and shortness of breath.\textsuperscript{42}

Currently, all of the available immunomodulatory agents must be injected. Because many patients find injections painful, difficult, and inconvenient, adherence may suffer. Mild, transient injection-site reactions, such as skin redness, reportedly occur commonly in patients receiving therapy via subcutaneous injection.\textsuperscript{48} More serious reactions, such as skin necrosis and lipoatrophy, are considerably less common. Skin necrosis has been reported in a small percentage of patients treated with IFN $\beta$-1b and IFN $\beta$-1a administered subcutaneously.\textsuperscript{48} Reports in the literature also indicate that glatiramer acetate has been associated with some instances of lipoatrophy at injection sites.\textsuperscript{63-66} Many of these injection-site reactions may be lessened or avoided with proper injection techniques and injection-site rotation. Patients receiving therapy via intramuscular injection (IFN $\beta$-1a) may also experience reactions at the injection site, including pain and bleeding following injection. Occasionally, patients receiving therapy via intramuscular injection have reported abscesses, which may necessitate surgical intervention and draining.\textsuperscript{48}

Fortunately, there are now different delivery systems for disease-modifying therapies that require self-injection. For example, autoinjection systems provide alternatives for patients who are needle-phobic and may also help to minimize injection-site reactions. All of the immunomodulatory agents are also available as prefilled syringes,\textsuperscript{42,59,62,67} which are especially convenient for patients with manual dexterity problems.\textsuperscript{48} IFN $\beta$-1b is also available as a room temperature–stable preparation, which may mean convenience for patients who frequently travel.\textsuperscript{62} Finally, researchers also are exploring the utility of sustained-release injectible formulations and alternative administration routes for administering immunomodulatory agents.

Although most of the side effects associated with the immunomodulatory agents diminish as treatment continues, they can undermine treatment adherence. A survey of participants in the CMSC/NARCOMS Registry—the registry of the North American Research Consortium on Multiple Sclerosis—demonstrated discontinuation rates ranging from 21% for patients treated with glatiramer acetate to 40% and 71% for patients treated with IFN $\beta$-1a administered via intramuscular injection and IFN $\beta$-1b, respectively.\textsuperscript{68} Key factors leading to the discontinuation of immunomodulatory therapies included increases in MS symptoms and flu-like symptoms associated with treatment. Less than 10% of registrants reported depression and skin reactions as reasons for discontinuing treatment. Interestingly, factors that were not considered adequate reasons for discontinuation included injection-site pain and self-injection or needing assistance with injection.\textsuperscript{68}

With regard to nursing roles in immunomodulatory treatment of MS, probably the most important nursing interventions are education and skill development. Patients and their families or care partners need to have a thorough understanding of the treatment options available to them, along with clear and realistic expectations of what the immunomodulatory agents can be expected to do. They also need to understand what side effects are associated with treatment and how these side effects can be managed. Nurses may want to use a checklist of questions for patients to consider when selecting an immunomodulatory treatment (Table 6).

Once a specific immunomodulatory agent has been chosen, patients need to know how to carry out the self-care aspects of their MS management plan. They will need training in reconstituting and injecting the medication. They may need help to overcome fear of needles and self-injection. Patients with memory deficits may need instruction in the use of specific memory cues to help them remember to take their medication on schedule.

Nurses play a key role in enhancing treatment adherence through patient education and by developing supportive relationships with patients, as mentioned earlier.
A great benefit of these drugs has been the hope they have brought to patients with MS—hope that can help to motivate self-care and adherence to treatment. Nurses must also monitor the patient’s response to immunomodulatory therapy, both initially and over time. If patients are having trouble adhering to treatment, the nurse should determine the source of the problem. If adherence problems are related to side effects, nurses can make practical suggestions for managing these effects. If side effects are intolerable, the patient may need to try a different immunomodulatory agent.

In addition, MS nurses often serve as advocates for patients who need immunomodulatory treatment. Nurses may interact with managed care organizations, insurance companies, and other health-benefit programs to help patients obtain treatment. As part of this advocacy effort, nurses may need to write letters describing the medical necessity of the immunomodulatory agents, and may need to assist with appeals against denial of benefits.

Other Disease-Modifying Therapies

A number of agents and strategies are being used or investigated for treatment of MS. Some can be given orally, such as azathioprine (Imuran®); others, including mitoxantrone (Novantrone®) and cyclophosphamide (Cytoxan®), are given intravenously.

Azathioprine, an immunosuppressive agent often used in transplant patients but also useful for the treatment of rheumatoid arthritis, lupus nephritis, and psoriatic arthritis, appears to reduce relapse frequency and decrease brain inflammation and lesion accumulation in patients with MS. However, some clinical trials have shown mixed results, along with severe side effects such as anemia and liver damage.

Mitoxantrone, an antineoplastic agent, has shown promise in treatment of MS. In phase III clinical trials, mitoxantrone given as an IV treatment every 3 months appeared to reduce relapse rates and the progression of disability in patients with advanced forms of relapsing-remitting and secondary-progressive MS.
used in combination with methylprednisolone in patients with signs of residual neurological deficits between relapses, primary and secondary end points such as the percentage of patients without new gadolinium-enhancing lesions, changes in EDSS scores, and annualized relapse rates improved significantly. However, with long-term use, mitoxantrone has dose-dependent cardiotoxic effects, and its dosage in MS patients is limited to a lifetime cumulative dose of 140 mg/m².

Cyclophosphamide, a potent immunosuppressive drug, has been used to treat MS for many years. Although cyclophosphamide sometimes improves the condition of patients with primary-progressive MS, recent studies have shown that any benefit is modest. In addition, cyclophosphamide can affect blood clotting and increase susceptibility to infection. One clinical trial has shown that cyclophosphamide may be of benefit to patients with MS who are rapidly deteriorating and have failed therapy with the interferons or glatiramer acetate.

Cladribine (Leustatin®) is an agent used to treat leukemia that may work by destroying activated lymphocytes. This agent, which is given intravenously, has shown some benefit in MS but has been associated with lymphopenia and herpes zoster infection. An oral agent is being considered for future investigation in MS.

Intravenous immunoglobulin (IVlg), a treatment that has been used as a “rescue therapy” for acute relapses, is being studied for its potential to reduce relapse rates and disability in MS. An earlier study demonstrated that in patients with relapsing-remitting MS, IVlg produced reductions in both relapse rate and the progress of disability, and had virtually no side effects. However, IVlg is extremely expensive and, therefore, may be impractical for long-term treatment until the evidence is stronger.

Although these treatments are used less frequently than the interferons and glatiramer acetate, nurses need to inform patients about their availability and their potential risks, benefits, and side effects. These novel and innovative strategies may offer hope to patients who have not responded to conventional treatments.
Supporting Multiple Sclerosis Nursing Practice Through Research

With the challenges presented by recent advances in technology and new therapeutic agents for MS, along with the continuous changes in the roles and responsibilities of MS nurses, nursing research is essential to documenting the effectiveness of nursing practice outcomes for patients with MS.77

Nursing research, performed as a systematic investigation or inquiry to generate new knowledge or validate existing knowledge, can contribute to the understanding of MS and its effects, guide nursing practice, and identify outcomes of effective nursing interventions. Nursing research may be quantitative or qualitative. It focuses on an illness or condition not purely as a health problem; rather, it examines the physical, emotional, and psychosocial responses of patients and their families to that illness or condition. Nursing research in MS may investigate patient and family responses anywhere along the illness trajectory and seeks to contribute in positive ways to shaping and managing the course of MS.

Nursing research has provided valuable information about caring for patients with MS. For example, recent studies have shown how patients experience and manage fatigue,78,79 the impact of illness uncertainty associated with MS on family life,80 and interventions that can help care partners manage stress.81 MS nurses can use this information in practical ways to gain perspective on their patients’ physical and emotional status and to encourage wellness, health-seeking strategies, and empowerment.

Several studies have examined factors that contribute to quality of life among people with MS. One investigation found that marriage, work, health status, and involvement in recreation or social activities are major contributors to a positive outlook.82 Several investigations by Fraser and colleagues have found that self-efficacy is a positive force in sustained adherence to complex therapies, pointing out that a belief that one can make a difference can sustain continued care.83,84 Another found that factors significantly related to perceived quality of life among patients with MS included involvement in health-promoting behaviors, including exercise, nutrition, and stress management, and taking responsibility for health.85

Two qualitative studies have examined patient experiences surrounding the diagnosis of MS19 and living with relapsing MS.86 Both studies employed phenomenological research methods — approaches used to understand people and their everyday lives under certain circumstances without including preconceived ideas.19 In the first study, researchers explored what five people experienced before, at the time of, and after diagnosis of MS.19 Before diagnosis, these people recalled searching for the reasons for their symptoms and creating possible explanations as a coping mechanism to protect themselves and others from undue anxiety. As symptoms recurred or worsened, patients experienced increasing concern about what might be wrong and entered a phase of worrying, wondering, and waiting for outcomes of consultations and testing. Once an MS diagnosis was confirmed, patients described feelings of shock and numbness that lasted only a few moments for some but days to weeks for others. Afterwards, there was the process of informing family members and others of the diagnosis, an experience that was not always positive. Finally, patients described “claiming” the diagnosis as part of adjusting and refocusing on plans and hopes for the future.

The second study examined the experiences of seven women and three men diagnosed with relapsing MS.86 With analysis of interview data, several themes emerged to describe patient experiences:
• Reliance on social networks
• Adjustment to MS
• Coping with symptoms and inconveniences
• Feelings of hope and hopelessness
• Need for control and independence
• Conflict with physicians, insurance companies, employers, family members
• Relief associated with confirmed diagnosis
• Uncertainty related to the unpredictability of MS
• Loss of independence, employment, relationships, function
• Fear of loss of health, life, support system
• Becoming informed about MS
• Struggle over revealing or concealing MS

Phenomenological studies such as these provide practical, “real-life” information that promotes empathy and understanding among healthcare professionals, thereby facilitating appropriate patient support.

Two exploratory nursing studies have examined the use of alternative therapies—including nutritional therapy, massage therapy, acupuncture, chiropractic treatment, and homeopathy—in small groups of patients who were not taking disease-modifying agents. The first study identified reasons why patients accessed alternative therapies, finding that most patients turned to these treatments because traditional medicine offered no cure. The second study examined relationships between the use of alternative therapies, symptom severity, and functional status. All patients reported reduction in MS symptom severity and improvement in functional status with the use of alternative therapies; however, the greater the number of therapies used, the lower the patients’ functional status scores. MS patients are often interested in alternative therapies, and findings from studies such as these can help nurses in their roles as counselors who help patients make appropriate treatment decisions.

A qualitative study investigation identified the information needs of patients experiencing relapses. The study found that these patients had significant gaps in their understanding of the physical symptoms they were experiencing and the drugs used to treat an acute relapse. Barriers to information access included both external barriers, such as limited computer or Internet access or difficulties accessing libraries, and internal barriers, such as denial, uncertainty, and fear. Results from this study suggest that patients with MS need relevant, specific, and current information to help them remain independent and to empower them to make informed decisions regarding relapse treatment.

Nursing research has identified specific physiological and psychological needs of care partners of patients with MS. Among the strongest needs identified by caregivers (who were usually spouses) was the need for regular; brief breaks from caregiving to allow rest and relaxation. In addition, all caregivers in the study reported that they received no help from community organizations. The same study asked caregivers how nurses can provide support. Caregivers stated that they needed more teaching about the disease process and the technical aspects of care and more current information on new developments in MS. Caregivers also wanted nurses to listen to and understand them.

**Limitations of Multiple Sclerosis Nursing Research**

To date, nursing research provides better understanding for MS nursing practice. However, nursing research is hampered by a variety of limitations. For example, there are no standardized definitions for terms such as caregiver or quality of life, and there are few tools with established validity or reliability for measuring outcomes of nursing interventions. Nursing research is also beset by minimal use of conceptual frameworks, small sample sizes, and sample heterogeneity. Many studies have been performed only once; confirmatory studies are needed. These issues mean that even for the research that has been done, interpretation across studies is difficult.

**Strategies to Facilitate Nursing Research: Buying Time**

Many nurses are overburdened with day-to-day responsibilities and are not expected or encouraged to take the time and effort that careful research would require. However, those nurses who wish to investigate a research question should and can begin to seek funding and support by:

• Identifying funding sources
• Developing grant-writing skills
• Identifying and developing collaborative relationships with other practitioners

Research funds are available from a variety of public and private sources, including those listed in Table 7. Additional information about funding for nursing research can be obtained through the Binghamton University Libraries Web site (http://library.lib.binghamton.edu/subjects/dynamic/?subject_id=14). The Foundation Center also provides grant information through its Web site (http://fdncenter.org).

Grant writing is a necessary aspect of obtaining funds for research. Writing a grant can be an intimidating prospect, but a variety of instructional programs and materials—including courses at colleges and universities, books, and Web sites—are helpful. The National Institutes of Health provide guidance on grant application procedures through their Web site (http://www.nih.gov). Many of the organizations that offer funds also provide specific instructions about how to prepare a grant proposal.

Another challenge in nursing research is patient recruitment. There are various approaches to patient recruitment, one of which is the CMSC/NARCOMS database. More information about access to this database can be obtained through the Consortium of Multiple Sclerosis Centers Web site (http://www.mscare.org).

An important benefit of nursing research is the professional recognition that comes with publication, whether in nursing journals or other health-related journals. Publication not only serves to release information valuable to the care of patients with MS but can enhance researchers’ chances of obtaining additional funding.

Often collaborative relationships are necessary to performing research. Nurses may need to form liaisons with other nurse researchers and with other professionals within or outside their practice or department to increase sample size, facilitate study design, acquire funding, and perform statistical analyses. In addition, collaborative efforts can facilitate clearance of research proposals through institutional review boards or research committees at hospitals or universities—often a necessary step in initiating research in many academic and medical school settings.

**Recommendations for Multiple Sclerosis Nursing Research**

In conducting research, nurses should be aware of certain practical issues. For example, they will need to identify appropriate statistical tests to validate and enhance data. Consultation with a statistician and the use of computer programs for statistical analysis will be beneficial. To ensure scientific rigor, investigators should use standardized assessment tools and outcomes measures that are objective and specific to nursing practice. Patients selected for a study should form balanced, homogeneous sample populations that are large enough to allow reasonable conclusions to be drawn. When appropriate, theoretical frameworks should guide study design. Replication studies can be important for confirming findings that have been published only once. Nurses also should follow ethical standards with regard to patient consent and confidentiality, conflict of interest issues, patent and copyright laws, and responsibilities of authorship when the time comes to prepare a manuscript.

**Research Priorities**

Published MS nursing research is sparse. There are many gaps and, clearly, no shortage of studies to pursue. Suggested areas for further study include the following:

- Impact of injection training on injection practices and injection-site reactions and infections
- Impact of autoinjection systems on patient adherence and injection-site reactions or infections
- Identifying the most effective educational approach to injection training
- Barriers to use of early therapy
- Factors that influence patients’ view of treatment
- Factors that influence adherence to treatment
- Women’s health issues, eg, MS-related issues in pregnancy, breast-feeding, parenting and child rearing, osteoporosis, and hormone replacement therapy with menopause
- Men’s health issues, eg, relationships between MS, MS treatments, and prostate cancer; responses to illness and treatment; and the impact of MS on parenting and professional roles
- Studies of symptom management using specific measurable outcomes to determine the most effective interventions
- Identifying the needs of patients (and their families) newly diagnosed with MS
- Identifying the needs of patients (and their families) with advanced MS
- Cultural influences and cultural responses to diagnosis, treatment, stresses, and coping
- Effect of MS on personal and family relationships (eg, children, couples) regarding issues such as disclosure of diagnosis
• Safety issues in MS, e.g., in relation to assistive technology, the home and work environment, and driving assessments

Findings from nursing studies can help broaden nurses’ knowledge and improve professional practice. There is a wealth of information to access within the environment of MS nursing practice, and research has the potential to provide valuable, practical information that can enhance the lives of patients affected by MS. Development of research skills could help improve nurses’ opportunities to obtain funding, design studies carefully, and implement systematic qualitative and quantitative investigations.

Conclusion

Rapid advances in technology and an ever-increasing range of effective medications, along with escalating healthcare costs, shorter hospital stays, and an increased emphasis on home care and patient self-care, have altered the practice environment significantly. With these changes have come a considerably greater amount of responsibility for nurses who care for patients with MS.

Clearly, nurses have an essential role to play in MS care, one that will continue to evolve. As the mechanisms underlying the development and progression of this disease are further understood, there will be more novel treatment strategies to optimize patient outcomes. Therefore, it is vital for nurses to constantly update themselves about MS care, research, and best practices in patient assessment and interventions. Nursing collaboration, expertise, and optimal access to care will support the MS team’s effort to fight the effects of this challenging and complex disease.
